Abstract—Computing platforms are evolving towards heterogeneous architectures including processors of different types and field programmable gate arrays (FPGAs), used as hardware accelerators for speeding up specific functions. The increasing capacity and performance of modern FPGAs, with their partial reconfiguration capabilities, have made them attractive in several application domains, including space applications.

This paper proposes a framework for supporting the development of safety-critical real-time systems that exploit hardware accelerators developed through FPGAs with dynamic partial reconfiguration capabilities.

A model is first presented and then used to derive a response-time analysis to verify the schedulability of a real-time task set under given constraints and assumptions. Although the analysis is based on a generic model, the proposed framework has been conceived to account for several real-world constraints present on today’s platforms and has been practically validated on the Zynq platform, showing that it can actually be supported by state-of-the-art technologies. Finally, a number of experiments are reported to evaluate the worst-case performance of the proposed approach on synthetic workload.

I. INTRODUCTION

Current computer architectures are evolving towards heterogeneous platforms consisting of hybrid computational devices that may include processors of different types and field programmable gate arrays (FPGAs). In particular, the reprogrammable and reconfigurable capabilities of FPGAs, their increasing capacity, and their suitability for signal processing have made them attractive in several application domains, as alternatives to application specific integrated circuits (ASICs) [1].

Xilinx [2] provided an analysis of recent progress in field programmable logic, highlighting that FPGAs have become bigger (comprising several million gates and up to a million bits of on-chip memory), faster (allowing system clock rates up to 200 MHz and I/O speed of up to 800 Mbits/second), more versatile (featuring dedicated carry structures to support adders, accumulators and counters), and cheaper, in terms of cost per logic gate.

Reprogrammable FPGA featuring high flexibility, combined with high performance and complexity are becoming increasingly important for space applications. With satellite lifetimes increased far beyond 10 years, re-programmability in flight becomes a stringent requirement. Moreover, in space environments, where radiation can cause bit flips in memory elements and ionisation failure in semiconductors, the use of reconfigurable hardware allows modifying on-board functions by replacing faulty/outdated designs at different stages of a mission.

Modern FPGA chips allow dynamic partial reconfiguration (DPR) capabilities, enabling the user to reconfigure a portion of the FPGA dynamically (at runtime), while the remainder of the device continues to operate [3]. This is especially valuable in mission-critical systems that cannot be disrupted while some subsystems are being redefined. In this context, mission-critical functions could continue to meet external interface requirements while other reconfiguration regions are reprogrammed to provide different functionality.

Partial reconfiguration is also useful in systems where multiple functions share the same FPGA resources. In such systems, one section of the FPGA continues to operate, while other sections are reconfigured to provide new functionality. Such an interesting capability opens a new scheduling dimension for applications running on heterogeneous platforms. As in multitasking, where multiple applications share the processors by switching contexts between software processes, DPR enables the possibility of interleaving multiple functions implemented as reprogrammable logic on an FPGA recurrently shared by different processing components. However, this is possible at the cost of reconfiguration times, which - today - are three orders of magnitude higher than context switch times in multitasking.

Despite this limitation, there is a clear evolution trend showing that reconfiguration times are progressively decreasing. Liu et al. [4] designed a smart reconfiguration peripheral interface, based on the Xilinx ICAP port [5], that is able to approach a throughput of 400 MB/s. Also, Duhem et al. [6] designed a fast reconfiguration interface by overclocking the ICAP port up to 200 MHz, corresponding to a throughput of 800 MB/s. An overview of the trend of reconfiguration times (obtained by comparing the theoretical maximum throughput calculated from platforms’ datasheets) is shown in Figure 1, based on the study conducted by Pagani et al. [7]. For this reason, it is plausible to expect that such a trend will continue in the upcoming years, thus making DPR a relevant direction to be explored.

Although reconfiguration times are not negligible, FPGAs allow hardware acceleration of a wide class of algorithms with a significant speedup factor [8], [9] over the corresponding sequential software implementation. For instance, in the case study analyzed in this work, a speedup factor up to 15x has been measured for an image processing filter implemented on the Zynq-7010 platform, which can reach a throughput of 145 MB/s for the DPR, allowing to reconfigure an FPGA area containing about 25% of the total resources in less than 3 milliseconds.

When exploiting FPGAs with DPR in real-time embedded systems, a crucial issue is to provide worst-case response time bounds of computations consisting of software tasks and hardware accelerated functions. Although several works have been done to analyze the timing behavior of real-time applications
using FPGAs, most of them did not consider DPR capabilities at a job level. To overcome this lack, this work proposes a new computing framework for enabling a timing analysis of real-time activities that make use of hardware accelerators developed through programmable FPGAs with DPR capabilities.

**Contributions.** This paper provides the following three main novel contributions:

1. It presents FRED, a framework for supporting real-time applications on FPGAs with DPR feature. It relies on a static off-line partitioning of the FPGA fabric to limit worst-case scenarios arising when using DPR. Design issues related to scheduling and inter-task communication are also discussed for bounding worst-case delays.
2. It proposes a new task model to abstract a set of real-time activities running on the considered architecture.
3. It derives a response-time analysis to verify the schedulability of a set of real-time tasks consisting of both software parts and hardware accelerated functions.

Although based on a generic modeling abstraction, the proposed framework has been conceived by considering several real-world constraints that are present on today’s platforms. In fact, FRED has been also practically validated with a proof-of-concept implementation on the Zynq platform [10]. Such a practical validation highlighted that the proposed approach can actually be supported by state-of-the-art technologies with a limited run-time overhead. Finally, to explore the worst-case performance of FRED, an empirical study (based on synthetic workload) has been conducted to evaluate the proposed response-time analysis under different operating scenarios.

**Paper organization.** The remainder of this paper is organized as follows. Section II presents a taxonomy of the different approaches and then discusses the related work. Section III describes the proposed framework and the related models. Section IV derives a response-time analysis for a set of tasks that use hardware acceleration. Section V presents some experimental results carried out on the Zynq platform to validate the proposed approach. Section VI reports a set of experiments aimed at evaluating the performance of the proposed response-time analysis on synthetic workload. Section VII concludes the paper and highlights some future work.

---

**Figure 1. Trend of reconfiguration throughput.**

The solutions proposed in the literature to exploit FPGA acceleration are quite heterogeneous due to the evolution of such platforms and the wide range of applications that can take advantage of this technology. The intrinsic parallelism, the reduced interference among the running activities, and the reduced variability in the execution made such a technology appealing for real-time applications, ranging from network management [11] to scheduling of hard [12] and soft [13] tasks. However, these solutions are limited to static or slowly evolving scenarios. Before analyzing the related work on DPR for real-time task scheduling, a taxonomy is first introduced to classify the existing solutions and precisely position the proposed approach with respect to the literature.

**Taxonomy.** The features considered to organize the taxonomy concern the reconfiguration approach, the allocation methods, the model of the FPGA reconfiguration interface (FRI), and the types of managed tasks.

**Reconfiguration approaches.** They can be distinguished between static and dynamic. In a static approach, the allocation of hardware tasks (HW-tasks) is performed at the initialization phase, while in a dynamic approach HW-tasks can be allocated at runtime upon specific events. Dynamic approaches can be used to support mode-changes in the application (allowing tasks to be added and removed from the task set) or trigger a reconfiguration every time a new job is scheduled (job-level reconfiguration). A static approach has no runtime reconfiguration overhead, but the maximum number of HW-tasks is limited by the physical size of the FPGA. Dynamic approaches trade extra reconfiguration overhead to increase the total number of HW-tasks that can be managed.

**Allocation methods.** They can be distinguished between slotted and slotless. In a slotted approach, the FPGA area is partitioned into slots of given size connected via buses provided on the static part of the FPGA. A HW-task can occupy one or more slots. In a slotless solution, HW-tasks can arbitrarily be positioned on the FPGA area and data are transferred through the reconfiguration interface inside the FPGA. Slotted approaches have the advantage of having the communication channels already in place, but the FPGA area may be partially wasted due to slot granularity. On the other hand, slotless solutions increase the utilization efficiency of the FPGA area, but are penalized by higher reconfiguration times due to the instantiation of communication channels and the increased traffic on the FRI due to the additional data transfer.

**FRI model.** The FRI plays a central role in FPGAs with DPR, thus, building a proper model of the FRI is crucial for estimating worst-case delays and enabling a real-time analysis. The easiest approach is to reduce complexity by considering reconfiguration delays negligible. This is a strong unrealistic assumption, considering that, in current FPGAs, reconfiguration delays can have the same order of magnitude of task execution times. A simple approximation can be obtained using a constant reconfiguration time. However, since the reconfiguration time is proportional to the number of elements to be reconfigured, and the FRI is a shared resource, providing a safe bound would introduce a huge pessimism in the analysis. Less pessimistic
values can be obtained considering the reconfiguration time composed by two elements: one proportional to the number of elements to be reconfigured and one due to the time spent in waiting for the FRI. Most of the works focused on kernel mechanisms considered an FRI model tailored to real solutions, as the Xilinx ICAP port [5].

Task model. Modern heterogeneous platforms include FPGAs modules together with processors on the same chip [14]. On such platforms it is thus possible to execute both HW-tasks, running on the FPGA, and software tasks (SW-tasks), running on the processors.

Related work analysis. The works considered in this section are related to the proposed approach in that they provide a timing analysis under reconfigurable FPGA architectures or propose a software support for HW-task management.

Di Natale and Bini [12] proposed an optimization method to partition the reconfigurable area of a homogeneous FPGA platform into slots to be allocated to HW-tasks and softcores running the remaining tasks. Given the high computational complexity of the method, this approach can only be used off-line to obtain a static task allocation, hence it does not exploit the advantages of the dynamic reconfiguration. Pellizzoni and Caccamo [15] addressed a similar problem in a more dynamic scenario, proposing an allocation scheme and an admission test to provide real-time guarantees of applications supporting mode changes, where tasks can either be executed in software on a CPU or in hardware on the FPGA.

Danne and Platzner [16] presented two algorithms (one EDF-based and one server-based) to schedule only preemptive HW-tasks, but the model adopted for the FPGA platform is quite simple and does not consider any reconfiguration time and allocation constraints. Saha et. al. [17] presented a new scheduling algorithm for preemptable HW-tasks, exploiting the higher speed and the improved capabilities of modern reconfiguration interfaces to dynamically change the allocation every time a task terminates. However, this approach assumes a homogeneous partition and a fixed reconfiguration time, which can lead to a huge waste of the area and a high pessimism in the analysis. In summary, in all the works cited above, the models used for the FPGA and the reconfiguration interface are too simple to describe the limitations of the available platforms, and the corresponding approaches do not fully exploit reconfiguration capabilities under real-time constraints.

Dittmann and Frank [18] addressed the analysis of reconfiguration requests as a single core scheduling problem. The paper assumes a single set of homogeneous slots managed by a non-preemptable FRI and considers only HW-tasks (SW-tasks are not taken into account). Unfortunately, due to missing proofs, it is not clear how response-time bounds follow. In addition, the authors did not investigate sustainability issues and their analysis may be affected by later-discovered misconceptions concerning non-preemptive fixed-priority scheduling [19].

Other authors proposed methods for supporting a job-level reconfiguration from a system perspective. The easiest solution is to communicate with a HW-task through proper software stubs that interact with the kernel scheduler and manage the HW-tasks at the application level. Another approach is to extend the operating system to provide specific primitives for scheduling, allocating, and programming HW-tasks, along with those related to SW-tasks management. For instance, Lübbers and Platzner [20] proposed the ReconOS operating system, which extends the classic multi-threading programming model to hardware activities executed on a reconfigurable device. Originally designed for fully reconfigurable FPGAs, this solution has then been extended by the same authors to support partial reconfiguration [21], with a cooperative multitasking approach to deal with slot contentsions. More recently, Happe et. al. [22] proposed an extension to the ReconOS execution environment to provide HW-tasks preemptability. However, its focus is on hardware enabling technologies, not on a kernel support for exploiting this capability. Iturbe et al. [23] presented the R3TOS operating system to support a more dynamic task allocation, exploiting the reconfiguration interface to avoid preconfigured static communication channels. The authors proposed a HW-task model and algorithms for their scheduling and allocation. However, a worst-case analysis is not provided and nothing is said on the schedulability of SW-tasks.

Although based on a more realistic FPGA model, the approaches considered in this second set of papers have been designed to improve the average system performance and focused on kernel implementation issues, without deriving worst-case response times bounds. As a consequence, these methods cannot be used for a real-time scheduling analysis.

Classification. Table I classifies the presented papers according to the proposed taxonomy, also highlighting the availability of a real-time analysis (RTA) to better emphasize the differences with respect to the proposed approach. Summarizing, different approaches have been proposed to exploit the advantages of DPR-enabled FPGAs, but none of them provided worst-case bounds for enabling a worst-case timing analysis of real-time sets of mixed HW-tasks and SW-tasks. In addition, most of the previous work did not consider heterogeneous FPGA slots. To overcome these limitations, the work proposed in this paper presents a heterogeneous slotted-based framework designed to make reconfiguration times more predictable and derive a schedulability analysis for real-time applications exploiting DPR capabilities. FPGA reconfiguration is managed at the job level and the schedulability analysis takes into account the delays and the constraints coming from the FRI. Both preemptive and non-preemptive reconfiguration are analyzed.

CLASSIFICATION OF THE RELATED WORK.

III. FRAMEWORK AND MODELING

This work considers a platform consisting of a processor and a DPR-enabled FPGA module that comprises b logic blocks.
The FPGA and the processor share a common memory \( \mathcal{M} \). The blocks of the FPGA module are statically partitioned into a set \( P = \{ P_1, ..., P_n \} \) of \( n \) partitions, where each partition \( P_k \) is composed of \( b_k \) logic blocks, with \( \sum_{k=1}^{n} b_k \leq b \). Blocks are not shared among partitions. Furthermore, each partition \( P_k \) is split into \( n_k^i \) slots of \( b_k^i \) logic blocks, such that \( \forall P_k \in P, n_k^i \cdot b_k^i \leq b_k \). Blocks are not shared among the slots.

As described in Section II, a slotted approach is more suitable for real-time systems because reconfiguration delays are shorter and more predictable than in a slotless solution, since there is no overhead related to task allocation management and to instantiation of communication channels. On the other hand, a slotted approach introduces a granularity that may increase the wasted area of the FPGA. This phenomenon can be mitigated by a proper design of slots and partitions as a function of the tasks. However, this issue is not addressed in this paper due to space limitations.

A. Hardware task model

The activities executed on the FPGA are modeled as a set \( \Gamma^H = \{ \tau_1^H, ..., \tau_n^H \} \) of \( n^H \) HW-tasks. Each HW-task \( \tau_i^H \) requires \( b_i \) logic blocks and has a worst-case execution time (WCET) \( C_i^H \). A HW-task can execute only if it has been programmed on a slot of the FPGA.

The considered platform is equipped with a FPGA reconfiguration interface (FRI) able to dynamically reconfigure a slot at run-time by programming a specific HW-task \( \tau_i^H \). Each slot can accommodate at most one HW-task \( [5], [24] \). As true in real-world platforms (such as [25], [26]), we assume that

(i) the FRI can reconfigure a slot without affecting the execution of the HW-tasks currently running in other slots;

(ii) no processor cycles are used for reconfiguring a slot (i.e., the FRI is an external peripheral, like DMA [14]); and

(iii) the FRI can program at most one slot at a time.

To program a given HW-task \( \tau_i^H \) into a slot, the FRI has to program all its logic blocks, independently of the number \( b_i \) of logic blocks required by \( \tau_i^H \), because unused blocks have to be disabled to “clean” the previous slot configuration.

Each HW-task \( \tau_i^H \) can be programmed in any of the slots belonging to a single partition. The partition hosting a HW-task \( \tau_i^H \) is denoted as \( P(\tau_i^H) \) and referred to as affinity. For all HW-tasks with affinity \( P(\tau_i^H) = P_k \), it must be \( b_i \leq b_k^i \).

The FRI is characterized by a throughput \( \rho \), meaning that \( \gamma_k^i = b_k^i/\rho \) units of time are needed to program a slot of a given partition \( P_k \). Hence, the time \( r_a \) needed to program a HW-task \( \tau_i^H \) is \( r_a = \gamma_k^i = P(\tau_i^H) = P_k \).

B. Software task model

The activities executed on the processor are modeled as a set \( \Gamma^S = \{ \tau_1^S, ..., \tau_n^S \} \) of \( n^S \) SW-tasks. Each SW-task can make use of HW-tasks to accelerate specific functions and is subject to timing constraints. In particular, each SW-task \( \tau_i \)

- uses a set \( \mathcal{H}(\tau_i) \subseteq \Gamma^H \) of \( n^H \) HW-tasks;
- alternates the execution of \( m_i + 1 \) sub-tasks (also referred to as chunks) with the execution of the \( m_i \) HW-tasks in \( \mathcal{H}(\tau_i) \); thus, the execution of a SW-task \( \tau_i \) can be represented as a sequence \( \tau_i := \{ \tau_{i,1}^H, \tau_{i,1}^H, \tau_{i,2}^H, \tau_{i,2}^H, ..., \tau_{i,m_i+1}^H \} \), where \( \{ \tau_{i,1}^H, \tau_{i,2}^H, ..., \tau_{i,m_i+1}^H \} \in \mathcal{H}(\tau_i) \) and \( \tau_{i,j} \) is the \( j \)-th sub-task of \( \tau_i \). Whenever the execution of a HW-task \( \tau_a^H \) is requested, the corresponding SW-task self-suspends until the completion of \( \tau_a^H \).

The beginning of the self-suspension phase coincides with the termination of the sub-task that issued a request for a HW-task. In a dual manner, the completion of a HW-task coincides with the release of the next sub-task.

- has a total WCET \( C_i \), composed of the WCETs \( C_{i,j} \) of all its sub-tasks \( \tau_{i,j} \); that is, \( C_i = \sum_{j=1}^{m_i+1} C_{i,j} \);
- is periodically (or sporadically) released with a period (or minimum inter-arrival time) of \( T_i \) units of time, thus generating an infinite sequence of execution instances (denoted as jobs);
- is subject to timing constraints; that is, each of its jobs must complete its execution within a deadline \( D_i \) relative to its activation time.

Each HW-task can be used by at most one SW-task, that is \( \bigcap_{\tau_i \in \Gamma^S} \mathcal{H}(\tau_i) = \emptyset \).

Figure 2 reports the pseudo-code defining the implementation skeleton of a SW-task \( \tau_i \) that uses \( m_i = 2 \) HW-tasks in the set \( \mathcal{H}(\tau_i) = \{ \tau_a^H, \tau_b^H \} \). The statement \(<..>\) has been used to represent a generic set of instructions that are part of a computation executed by the SW-task on the processor.

```
1 TASK(\tau_i)
2 {
3    <..>
4    <prepare input data for \tau_a^H>;
5    EXECUTE_HW_TASK(\tau_a^H);
6    <retrieve output data from \tau_a^H>;
7    <..>
8    <prepare input data for \tau_b^H>;
9    EXECUTE_HW_TASK(\tau_b^H);
10   <retrieve output data from \tau_b^H>;
11   <..>
12 }
```

Figure 2. Pseudo-code of the implementation skeleton of a SW-task.

The SW-task illustrated in Figure 2 is described by the sequence \( \{ \tau_{i,1}^H, \tau_{i,1}^H, \tau_{i,2}^H, \tau_{i,2}^H, \tau_{i,3}^H \} \): the first sub-task \( \tau_{i,1} \) consists of lines 3-5, the second sub-task \( \tau_{i,2} \) of lines 6-9 and the third sub-task \( \tau_{i,3} \) of lines 10-11. \( \text{EXECUTE_HW_TASK}(\tau_a^H) \) is a blocking system call, which is in charge of (i) requesting the execution of \( \tau_a^H \) and (ii) suspending the execution of \( \tau_i \) until the completion of \( \tau_a^H \). Note that at line 4, \( \tau_{i,1} \) prepares the input data for \( \tau_a^H \). Similarly, \( \tau_{i,2} \) retrieves the output data produced by \( \tau_a^H \) (line 6) and prepares the input data for \( \tau_b^H \) (line 8). Further details on the inter-task communication mechanism are discussed in Section III-D.

Figure 3 illustrates the execution behavior of another SW-task \( \tau_{i+1} := \{ \tau_{i+1,1}^H, \tau_{i+1,2}^H, \tau_{i+1,2}^H \} \), visualizing the delays experienced when requesting the execution of \( \tau_a^H \).

Figure 3. Execution behavior of a SW-task calling a HW-task.
As clear from the figure, task $\tau_i$ is activated at time $t_0$. At time $t_1$, the first sub-task $\tau_{i,1}$ requests the execution of the HW-task $\tau_{a,H}^i$ and self-suspends its execution at time $t_2$, where $(t_2 - t_1)$ corresponds to the system overhead to issue the request. This example assumes that all the slots of partition $P(\tau_{a,H}^i)$ are busy (i.e., occupied by other HW-tasks that are currently executing), hence a delay $\Delta_a$ is introduced from time $t_2$ until time $t_3$, at which one slot of $P(\tau_{a,H}^i)$ becomes free. Once there is a free slot in $P(\tau_{a,H}^i)$, the HW-task can be programmed, from time $t_3$ to $t_4$, by using the FRI: such an operation takes at most $r_a$ units of time, where $r_a = b_a^i/\rho$ (being $k$ the affinity of $\tau_{a,H}^i$).

After the programming phase, $\tau_{a,H}^i$ starts executing at time $t_4$ on the FPGA and completes at time $t_5$ within $C_a^H$ units of time. Then, the SW-task is resumed and executes the second sub-task $\tau_{i,2}$, which completes at time $t_6$. Note that $\tau_i$ is suspended for the interval $[t_2, t_3]$, which is no longer than $S = \Delta_a + r_a + C_a^H$.

While the example presented above has a single SW-task, the system considered in this paper includes multiple SW-tasks and HW-tasks that contend the resources available on the platform. This means that a SW-task $\tau_i$ can suffer a temporal interference from the execution of other SW-tasks that, if not properly managed, can determine the violation of its deadline $D_i$. Such interference also depends on the contention for the FPGA slots and the FRI caused by the other HW-tasks. For such reasons, a scheduling infrastructure is needed to support a set of concurrent HW-tasks and SW-tasks.

C. Scheduling infrastructure

Each SW-task $\tau_i$ is assigned a fixed priority $\pi_i$, also inherited by all its sub-tasks. A SW-task is denoted as ready when (i) it has a pending job (i.e., a job released but not yet completed) and (ii) it is not self-suspended waiting for the completion of a HW-task. SW-tasks are assumed to be scheduled according to a fixed-priority (FP) preemptive scheduling algorithm, so that, at any point in time, the ready task with the highest priority is executed on the processor.

Besides the processor, two other resources are contented by SW-tasks: the slots in the FPGA partition (shared with other HW-tasks having the same affinity) and the FRI. Hence, multiple requests for such resources have to be scheduled. The overall scheduling infrastructure managing the slots and the FRI is based on a multi-level queue structure, illustrated in Figure 4.

We begin by describing the scheduling policies used for each resource; then, we present the scheduling rules that apply to every request for HW-tasks when traversing the multi-level queue structure of Figure 4.

Slot scheduling. For the purpose of scheduling, each slot can be free or busy. A busy slot can in turn be active, when there is a HW-task programmed on it that is executing, or reserved. A HW-task $\tau_{i,H}$ with affinity $P(\tau_{i,H}^i) = P_k$, that is waiting for a free slot in partition $P_k$, is kept in a queue $Q_k$ managed according to a first-in-first-out (FIFO) policy. Note that such a scheduling policy guarantees a starvation-free progress mechanism. Moreover, it does not require preempting the execution of HW-tasks, which is known to be a challenging issue [27] [18] leading to non-negligible run-time overheads.

FRI scheduling. Whenever there are $x$ free slots into a given partition $P_k$, such $x$ slots are reserved for the first $x$ HW-task requests waiting into $Q_k$ which then have to contend the FRI to program their corresponding HW-task. While slots are shared only among the HW-tasks belonging to the same partition, the FRI is a single resource contented by all the requests for HW-tasks in the system. HW-task requests contending the FRI are kept in a queue denoted as $Q^{FRI}$.

In this paper, slot programming requests are managed according to a ticket-based scheduling policy, which is described below and can be configured to be executed either in a preemptive or non-preemptive fashion. Please note that HW-task execution is assumed to be non preemptive to contain the preemption overhead associated to FPGA reconfigurations. Hence, here preemptive and non-preemptive policies are only related to the FRI programming phase. Under a non-preemptive policy, the programming phase cannot be interrupted, whereas under a preemptive policy, the programming phase can be interrupted to serve another programming request.
Ticket-based scheduling. The ticket-based scheduling policy is described by the following rules that apply to both non-preemptive and preemptive management of the FRI:

R1 Each execution request \( R_a \) for an HW-task \( \tau_a^H \) is assigned a “ticket” marked with the absolute time \( t(R_a) \) at which \( R_a \) has been issued.

R2 Every partition queue \( Q_k \) and the FRI queue \( Q^{FR1} \) enqueue execution requests for HW-tasks by increasing ticket time.

R3 When a request \( R_a \) for HW-task \( \tau_a^H \) is issued, \( R_a \) is inserted in the partition queue \( Q_k \) with \( P_k = P(\tau_a^H) \).

R4 At any point in time \( t \), for every partition queue \( Q_k \), the first \( \eta_k(t) \geq 0 \) requests in \( Q_k \) are removed from \( Q_k \) and inserted in \( Q^{FR1} \), where \( \eta_k(t) \) is the number of free slots in \( P_k \) at time \( t \). Contextually, these \( \eta_k(t) \) slots become reserved (and hence busy).

R5 Once the HW-task \( \tau_a^H \) related to a request \( R_a \) has been programmed onto a slot, \( R_a \) is removed from \( Q^{FR1} \), that slot becomes active, and \( \tau_a^H \) starts executing.

R6 When a HW-task \( \tau_a^H \) completes its execution, the corresponding slot becomes free.

The following scheduling rules distinguish between non-preemptive and preemptive management of the FRI. In the case of preemptive FRI scheduling, the following rule holds:

R-P1 Whenever \( Q^{FR1} \) is not empty, the FRI programs the HW-task related to the first request in \( Q^{FR1} \) (i.e., the one having the earliest ticket time).

For non-preemptive FRI scheduling the following rules hold:

R-NP1 When the FRI is programming a HW-task it cannot be interrupted to serve another request.

R-NP2 When the FRI completes a programming phase, or \( Q^{FR1} \) becomes not empty, the FRI starts programming the HW-task related to the first request in \( Q^{FR1} \).

Example. Figure 5 shows an example of preemptive FRI management schedule under FRED for an FPGA module containing two partitions \( P_1 \) and \( P_2 \), each consisting of a single slot.

The application consists of three SW-tasks: \( \tau_1 = \langle \tau_{1,1}, \tau_{1,2}, \tau_{1,3} \rangle \), \( \tau_2 = \langle \tau_{2,1}, \tau_{2,2} \rangle \), and \( \tau_3 = \langle \tau_{3,1}, \tau_{3,2} \rangle \). The priority assignment is such that \( \pi_1 > \pi_2 > \pi_3 \). HW-tasks \( \tau_a^H \) and \( \tau_b^H \) share partition \( P_1 \) (i.e., \( P(\tau_a^H) = P(\tau_b^H) = P_1 \)), whereas HW-tasks \( \tau_c^H \) and \( \tau_d^H \) share partition \( P_2 \) (i.e., \( P(\tau_c^H) = P(\tau_d^H) = P_2 \)).

All the SW-tasks are synchronously released at time \( 0 \). Being the highest-priority one, \( \tau_1 \) starts executing as first and at time \( t = 1 \) completes its sub-task \( \tau_{1,1} \) by issuing a request \( R_a \) for HW-task \( \tau_a^H \). Contextually, \( \tau_1 \) self-suspends its execution. According to Rule R3, \( R_a \) is inserted in the partition queue \( Q_1 \). Since partition \( P_1 \) is empty, at time \( t = 1 \) there is a free slot \( (\eta_1(1) = 1) \); hence, according to Rule R4, \( R_a \) is moved to \( Q^{FR1} \) and the slot of \( P_1 \) becomes reserved. Moreover, according to Rule R-P1, the FRI starts programming \( \tau_a^H \). At time \( t = 5 \), \( \tau_a^H \) has been programmed and according to Rule R5 it starts executing.

At time \( t = 1 \), \( \tau_2 \) starts executing being the highest-priority SW-task ready. At time \( t = 2 \), \( \tau_2 \) concludes its sub-task \( \tau_{2,1} \) by issuing a request \( R_c \) for \( \tau_c^H \). According to Rule R3, \( R_c \) is inserted in the partition queue \( Q_2 \). Since partition \( P_2 \) is empty, at time \( t = 2 \) there is free slot \( (\eta_2(2) = 1) \); hence, according to Rule R4, \( R_c \) is moved to \( Q^{FR1} \) and the slot of \( P_2 \) becomes reserved. However, since \( R_c \) has a later ticket time than \( R_a \), \( R_c \) is delayed until \( \tau_c^H \) has been programmed (time \( t = 5 \)). Then, \( \tau_c^H \) can be programmed and be executed.

At time \( t = 2 \), \( \tau_3 \) is the highest-priority SW-task ready, thus it starts executing until time \( t = 3 \), when it terminates its first sub-task \( \tau_{3,1} \) by issuing a request \( R_d \) for \( \tau_d^H \). According to Rule R3, \( R_d \) is inserted in the partition queue \( Q_2 \). However, being the slot of \( P_2 \) busy (specifically, reserved in \( [5,7] \) and active in \( [7,\infty] \)), \( R_d \) waits in \( Q_2 \) until time \( t = 11 \). At time \( t = 11 \), \( \tau_d^H \) completes its execution, Rule R6 is applied and the slot of \( P_2 \) becomes free. According to Rule R4, \( R_d \) is moved to \( Q^{FR1} \), the slot of \( P_2 \) becomes again busy (specifically, reserved) and \( \tau_d^H \) starts to be programmed.

Now, consider again \( \tau_1 \). At time \( 9 \), \( \tau_a^H \) is completed and hence the sub-task \( \tau_{1,2} \) can be released. At time \( 10 \), \( \tau_{1,2} \) completes by issuing a request \( R_b \) for HW-task \( \tau_b^H \). By Rule R3 and Rule R4, \( R_b \) is inserted into \( Q^{FR1} \). Being \( Q^{FR1} \) empty, \( \tau_b^H \) starts to be programmed. However, as explained above, at time \( t = 11 \), \( R_d \) (issued by \( \tau_3 \)) is inserted into \( Q^{FR1} \). Being \( t(R_d) = 3 < t(R_b) = 10 \), according to Rule-R-P1 the programming of \( \tau_b^H \) is preempted to program \( \tau_d^H \) until time \( t = 13 \). Hence in \( [11,13) \) \( R_b \) is delayed. Finally, note that the FRI queue is not managed in a pure FIFO manner.

D. Communication between SW and HW tasks

As stated in Section III-B, SW-tasks make use of HW-tasks to accelerate specific computations; that is, a SW-task offloads a computation to the FPGA by requesting the execution of a HW-task and then retrieves the output of such a computation to continue the execution on the processor. As shown in Figure 2, the communication between a SW-task \( \tau_i \) and a HW-task \( \tau_a^H \) includes two phases:

(i) sub-task \( \tau_{i,j} \) prepares the input data for \( \tau_a^H \);
(ii) sub-task \( \tau_{i,j+1} \) retrieves the data produced by \( \tau_a^H \).

It is worth observing that the approach used to enable such a communication can affect the real-time performance of the sys-
tem by introducing different worst-case scenarios. For instance, suppose that the output data produced by a HW-task are stored in its internal memory area and that phase (ii) comprises a copy from the local memory of the HW-task to a memory area accessible by the SW-task. In such a case, the HW-task must remain programmed onto the FPGA module until the sub-task in charge of executing the phase (ii) will be executed, otherwise output data would be lost.

Due to the scheduling delays suffered by SW-tasks, the actual time a HW-task occupies a slot is hence dependent on SW-tasks’ execution behavior. Longer slot occupation times increase the delays suffered by HW-tasks, which in turn increase the delays suffered by SW-tasks by inflating their suspension time when waiting for the completion of a HW-task. Such a circular dependency can originate pathological scenarios that significantly increase the worst-case response time of SW-tasks, thus making this approach not attractive for a real-time system.

To overcome this problem, FRED adopts a different approach inspired by the capabilities of state-of-the-art platforms, where the communication between SW-tasks and HW-tasks is supported by allowing HW-tasks to directly access the shared memory \( M \). Hence, the two communication phases are implemented as follows:

(i) sub-task \( \tau_{i,j} \) prepares the input data for \( \tau_{a}^H \) in a memory area \( M_{a}^{IN} \) inside \( M \), and \( \tau_{a}^H \) retrieves the input data by directly accessing \( M_{a}^{IN} \);

(ii) \( \tau_{a}^H \) stores the output data into a memory area \( M_{a}^{OUT} \) inside \( M \), and \( \tau_{i,j+1} \) retrieves them directly from \( M_{a}^{OUT} \), hence \( \tau_{a}^H \) can release its slot as it finishes.

References (i.e., memory pointers) to both \( M_{a}^{IN} \) and \( M_{a}^{OUT} \) are assumed to be provided to the HW-task or known a priori. By adopting this solution, the time \( \tau_{a}^H \) must hold a slot is totally decoupled from the scheduling delays of SW-tasks and is always upper-bounded by the WCET \( C_{a}^H \) plus the slot reconfiguration time \( r_a \).

As done in most real-time analysis, bus contention times due to the interaction between HW-tasks and SW-tasks can be accounted in the WCETs. Finally, please note that such a communication approach is not limited to platforms having a main memory shared between the processor and the FPGA module, but it can also be used in platforms where a dedicated memory is reserved for such a communication. Indeed, the latter solution is more suitable for safety-critical systems requiring a higher level of predictability.

IV. Real-Time Analysis

The goal of this section is to derive a sufficient response-time analysis for the SW-tasks running under FRED. That is, for each SW-task \( \tau_i \), this section provides an upper-bound \( R_i \) on its maximum response-time such that the system is guaranteed to be schedulable if

\[
\forall \tau_i \in \Gamma^S, \ R_i \leq D_i.
\]

The upper-bounds are derived by building on Nelissen et al.’s [28] response-time analysis for real-time fixed-segment self-suspending tasks (SS-tasks). The SS-task model is a generic model for real-time computational activities where multiple execution phases are alternated to self-suspension phases, exactly like the execution behavior of the SW-tasks under FRED. Similarly to a SW-task, a SS-task \( \tau \) alternates the execution of \( m_{\ell} + 1 \) sub-tasks, each having WCET \( C_{\ell,j} \) (\( j \) goes from 1 to \( m_{\ell} + 1 \)) and \( m_\ell \) suspension phases, each lasting at most \( S_{\ell,j} \) time units (\( j \) goes from 1 to \( m_\ell \)). The \( C, T \) and \( D \) parameters of a SS-task are consistently defined as the corresponding ones of a SW-task, as stated in Section III-B.

Each SW-task \( \tau_i \) can hence be mapped (i.e., translated) into a SS-task \( \tau_{\ell} \) according to the following rules:

1) \( C_{\ell,j} = C_{i,j}, \ \forall j = 1, \ldots, m_{\ell} + 1 \);

2) \( S_{\ell,j} = r_a + C_{a}^H + \Delta_a, \ \forall j = 1, \ldots, m_{\ell} \), where \( \tau_a^H \in H(\tau_i) : \tau_i := (\ldots, \tau_{k,j}, \tau_{a}^H, \tau_{k,j+1}, \ldots) \).

3) unless differently specified, \( X_{\ell} = X_i \), where \( X_i \) is a parameter of \( \tau_i \).

Intuitively speaking, Rule 1 maps each sub-task of the SW-task \( \tau_i \) into a sub-task of the SS-task \( \tau_{\ell} \), while Rule 2 defines a suspension phase of the SS-task for each HW-task \( \tau_a^H \) used by \( \tau_i \); such a suspension phase includes the reconfiguration time \( r_a \), the WCET \( C_{a}^H \) and the the worst-case delay \( \Delta_a \) suffered by the HW-task under the FRED scheduling infrastructure. Finally, Rule 3 enforces that the other parameters of the SS-task \( \tau_{\ell} \) are equal to the ones of the SW-task \( \tau_i \).

Please note that all the parameters mentioned in the rules above are known, except for the delay \( \Delta_a \); computing a safe upper-bound on such a delay is the main challenge of the proposed real-time analysis.

For the sake of completeness, the next section briefly summarizes the Nelissen et al.’s response-time analysis for SS-tasks.

A. Summary on Nelissen et al.’s analysis

The response-time analysis of fixed-priority SS-tasks is a problem studied since several years in the real-time community. However, Nelissen et al. [28] discovered several errors in many papers concerning the analysis of SS-tasks, proving that most of the published results are not safe and proposing a safe and accurate response-time analysis for SS-tasks based on mixed-integer linear programming (MILP).

A MILP formulation is instantiated for each SS-task \( \tau_{\ell} \) whose objective is to maximize the response-time upper-bound \( R_{\ell,j} \) of each sub-task \( \tau_{\ell,j} \) composing \( \tau_{\ell} \). Each response-time upper-bound is expressed as \( R_{\ell,j} = C_{\ell,j} + \sum_{\tau_k \in \text{hp}(\tau_{\ell})} \sum_{k,z} N_{I_{k,z}} \times C_{k,z} \) where \( \text{hp}(\tau_{\ell}) \) is the set of tasks that have higher priority than \( \tau_{\ell} \) and \( N_{I_{k,z}} \) is an integer optimization variable modeling the number of jobs of \( \tau_{\ell,j} \) interfering with \( \tau_{\ell} \). Several constraints are enforced to bound the value of \( N_{I_{k,z}} \); please refer to [28] for further details. Finally, once the MILP has been solved, the total response-time upper-bound \( R_{\ell} \) of \( \tau_{\ell} \) is computed as \( R_{\ell} = \sum_{\ell,j=1}^{m_{\ell}} R_{\ell,j} + \sum_{j=1}^{m_{\ell}-1} S_{\ell,j} \).

B. Upper-bound for the delay \( \Delta_a \)

As stated above, computing a response-time upper-bound for SW-tasks is crucial to bound the maximum time a SW-task can be suspended to wait for the completion of a HW-task. This in turn requires bounding the delay \( \Delta_a \) suffered by each HW-task request \( R_a \), which is the goal of this section.

As a first step, the following lemma establishes that the ticket-based scheduling policy introduced in Section III-C is work-conserving.
Lemma 1: A HW-task request $\mathcal{R}_a$ for $\tau_a^H$ with affinity to partition $P_k = P(\tau_a^H)$ is delayed at time $t$ if and only if either

- all the $n_k^S$ slots of $P_k$ are busy serving other HW-tasks $\tau_b^H \neq \tau_a^H$ with $P(\tau_b^H) = P_k$;
- or the FRI is busy programming other HW-tasks $\tau_b^H \neq \tau_a^H$.

Proof: A HW-task request $\mathcal{R}_a$ can be delayed either (i) when it is in the partition queue $Q_\mathcal{R}_a$ or (ii) when it is in the $Q^{FRI}$ queue. In case (i), according to Rule 4, $\mathcal{R}_a$ can wait as long as all the $n_k^S$ slots of $P_k$ are busy. In case (ii), we distinguish between preemptive and non-preemptive FRI management. Under preemptive FRI management, being $Q^{FRI}$ non-empty (at least $\mathcal{R}_a$ is inside $Q^{FRI}$), by Rule R-P1 the FRI is still programming a HW-task $\tau_b^H$ in a reserved slot in $P(\tau_b^H)$. By Rule R4, for every request inserted into $Q^{FRI}$ there is a reserved slot in the corresponding partition. The same argument holds under non-preemptive FRI management by considering Rules R-NP1 and R-NP2.

By relying on the fact that SW-tasks issue HW-task requests in a sequential fashion, it is possible to establish another key property.

Lemma 2: Let $\mathcal{R}$ be an arbitrary HW-task request issued by a SW-task $\tau_i$ at time $t(\mathcal{R})$ and let $t_s(\mathcal{R})$ be the time at which $\mathcal{R}$ is removed from $Q^{FRI}$ (i.e., $\mathcal{R}$ is satisfied). Let also $pend(\mathcal{R})$ be the set of pending HW-task requests during $[t(\mathcal{R}), t_s(\mathcal{R})]$ that have earlier (or equal) ticket time, i.e., $\forall \mathcal{R}_a \in pend(\mathcal{R}), t(\mathcal{R}_a) \leq t(\mathcal{R})$. If HW-task requests are serialized as specified in the model presented in Section III-B, then each SW-task $\tau_j \neq \tau_i$ can possibly issue at most one HW-task request in $pend(\mathcal{R})$.

Proof: By contradiction. Suppose that $pend(\mathcal{R})$ contains more than one HW-task request from SW-task $\tau_j$, say $\mathcal{R}_a$ and $\mathcal{R}_b$, respectively issued at times $t(\mathcal{R}_a)$ and $t(\mathcal{R}_b)$ and satisfied at times $t_s(\mathcal{R}_a)$ and $t_s(\mathcal{R}_b)$. Without loss of generality assume $t(\mathcal{R}_a) \leq t(\mathcal{R}_b)$. By definition of set $pend(\mathcal{R})$ we have $t(\mathcal{R}_a) \leq t(\mathcal{R})$, $t_s(\mathcal{R}_a) > t(\mathcal{R})$ and $t_s(\mathcal{R}_a) > t(\mathcal{R})$. Hence we obtain $t(\mathcal{R}_a) \leq t(\mathcal{R}_b) \leq t(\mathcal{R}) < t_s(\mathcal{R}_a)$, which implies that $\mathcal{R}_b$ has been issued before the completion of $\mathcal{R}_a$. This contradicts the assumption, according to which HW-task requests issued by the same SW-task are serialized. Hence, the lemma follows.

We are now ready to derive the upper-bound for the delay $\Delta_a$. To this end, it is necessary to distinguish between preemptive and non-preemptive management of the FRI.

1) Preemptive FRI management:

Theorem 1: Consider an arbitrary HW-task request $\mathcal{R}_a$ for $\tau_a^H$ issued by a SW-task $\tau_i$. Let $P_{in} = P(\tau_i^H)$ be the affinity of $\tau_i^H$. Under preemptive management of the FRI, the maximum delay $\Delta_a$ incurred by $\mathcal{R}_a$ is upper-bounded by

$$\Delta_a^P = \max_{\tau_j \neq \tau_i, \tau_b^H \in H(\tau_j)} \left\{ \Delta_a^{slot} + r_b \right\}$$

where

$$\Delta_a^{slot} = \begin{cases} C^H_{\mathcal{R}_a} & \text{if } P(\tau_b^H) = P_k \\ 0 & \text{otherwise.} \end{cases}$$

Proof: Let $X$ be the set of HW-task requests that delay $\mathcal{R}_a$. Since we are considering preemptive management of the FRI, Rule R-P1 applies. Because of such a rule and the FIFO ordering of the partition queue $Q_k$, $\mathcal{R}_a$ can only be delayed by other requests that have earlier (or equal) ticket time. Hence, $\forall R \in X, t(\mathcal{R}) \leq t(\mathcal{R}_a)$.

To help the presentation we define the set of HW-tasks $\Gamma_k^H$ by mapping each HW-task request $\mathcal{R} \in X$ into the corresponding HW-task $\tau_k^H$ in $\Gamma_k^H$. By Lemma 2, each SW-task $\tau_j \neq \tau_i$ can have issued at most one HW-task request in $X$. Hence, $\forall \tau_j \neq \tau_i, |\Gamma_k^H \cap H(\tau_j)| \leq 1$. Moreover, since one HW-task cannot be used by multiple SW-tasks (i.e., $\bigcap_{\tau_j \neq \tau_i} H(\tau_j) = \emptyset$), each request in $X$ corresponds to one and only one HW-task in $\Gamma_k^H$, hence $|\Gamma_k^H| = |X|$.

The total workload $W$ that can delay $\mathcal{R}_a$ cannot be greater than the sum of (i) the execution time of HW-tasks in $\Gamma_k^H$ and (ii) the reconfiguration time of HW-tasks in $\Gamma_k^H$. In addition, by Lemma 1, $\mathcal{R}_a$ cannot be delayed by the execution of HW-tasks $\tau_b^H$ with $P(\tau_b^H) \neq P_k$. Hence, we have

$$W \leq \sum_{\tau_b^H \in \Gamma_k^H, P(\tau_b^H) = P_k} C^H_{\mathcal{R}_a} + \sum_{\tau_b^H \in \Gamma_k^H, P(\tau_b^H) \neq P_k} r_b,$$

and being HW-task requests scheduled in a work-conserving manner (by Lemma 1), $\Delta_a \leq W$ holds.

Now, note that any interval in which $\mathcal{R}_a$ is delayed can be considered as an alternating sequence of sub-intervals of two types:

(i) type X: if $Q^{FRI}$ contains at least a request with a ticket time less than $t(\mathcal{R}_a)$, i.e., $\exists R \in Q^{FRI} : t(R) \leq t(\mathcal{R}_a)$;
(ii) type Y: otherwise, i.e., $\forall R \in Q^{FRI} : t(R) \leq t(\mathcal{R}_a)$.

Being such intervals complementary, this classification is well defined.

Let $\Delta_X$ be the total delay suffered by $\mathcal{R}_a$ during intervals of type X and let $\Delta_Y$ be the one suffered during intervals of type Y. Hence, the total delay is given by $\Delta_a = \Delta_X + \Delta_Y$. To derive a bound on $\Delta_a$, we proceed by deriving a bound on each of these two terms.

Type X) Consider an arbitrary time instant during an interval of type X. Let $\mathcal{R}$ be the request at the head of $Q^{FRI}$. By definition of type X interval and Rule R2, $t(\mathcal{R}) \leq t(\mathcal{R}_a)$; hence $\mathcal{R}$ contributes to the workload $W$. According to Rule R-P1, the FRI is programming the HW-task related to $\mathcal{R}$, and hence $\mathcal{R}_a$ is delayed anyhow by such an operation.

In total, $\mathcal{R}_a$ cannot be delayed by more than the overall reconfiguration times in the workload $W$, hence $\Delta_X \leq \sum_{\tau_b^H \in \Gamma_k^H} r_b$.

Type Y) In this case, the queue $Q^{FRI}$ can be empty or non-empty. If $Q^{FRI}$ is empty, being $\mathcal{R}_a$ delayed, it must be waiting into its partition queue $Q_k$. If $Q^{FRI}$ is non-empty, $\mathcal{R}_a$ cannot be into $Q^{FRI}$ otherwise it would not be delayed according to Rule R2 and Rule R-P1 (i.e., it would be at the head of $Q^{FRI}$); hence $\mathcal{R}_a$ is waiting in $Q_k$ anyway.

According to Rule 4, if $\mathcal{R}_a$ waits into $Q_k$, then all the $n_k^S$ slots of $P_k$ are busy. Moreover, none of these slots can be reserved: this holds because of the FIFO ordering of $Q_k$ (in fact no request with affinity $P_k$ can be into $Q^{FRI}$). Hence, in this case, all the $n_k^S$ slots of $P_k$ are active serving the execution of HW-tasks $\tau_b^H$ with $P(\tau_b^H) = P_k$. As a consequence, if $\mathcal{R}_a$ is delayed by $\Delta_Y$ time units across all intervals of type Y, then partition $P_k$ served $n_k^S \cdot \Delta_Y$ execution time units.
By looking at the workload \( W \) that can interfere with \( R_a \), it must be that
\[
n_k^S \cdot \Delta^Y \leq \sum_{\tau^H_k \in \Gamma^H_k} C^H_k
\]
and hence
\[
\Delta^Y \leq \sum_{\tau^H_k \in \Gamma^H_k} \frac{C^H_k}{n_k^S} + \tau^H_k
\]
Rewriting the expression for \( \Delta_a \), we obtain
\[
\Delta_a = \Delta^X + \Delta^Y \leq \sum_{\tau^H_k \in \Gamma^H_k} \left( \frac{C^H_k}{n_k^S} + \tau^H_k \right) + \sum_{\tau^H_k \in \Gamma^H_k} \tau^H_k.
\]

The upper-bound on \( \Delta_a \) follows by maximizing Equation (3) over all possible sets \( \Gamma^H_k \). Since by construction of \( \Gamma^H_k \) each SW-task \( \tau_j \neq \tau_i \) can have at most one request for a HW-task \( \tau^H_k \in \Gamma^H_k \), Equation (2) accounts for the maximum contribution to Equation (3) given by each SW-task \( \tau_j \neq \tau_i \).

2) Non-preemptive FRI management: Building on the bound \( \Delta_a^P \) stated by Theorem 1, it is possible to derive a bound on the delay incurred in the case of non-preemptive FRI.

Theorem 2: Consider an arbitrary HW-task request \( R_a \) for \( \tau^H_k \) issued by a SW-task \( \tau_i \). Let \( P_k = P(\tau^H_k) \) be the affinity of \( \tau^H_k \). Under non-preemptive management of the FRI, the maximum delay \( \Delta_a \) incurred by \( R_a \) is upper-bounded by
\[
\Delta_a^P = \Delta_a^P + N H_{k}^{\max} \times r_{k}^{\max}
\]
where
\[
N H_{k}^{\max} = \left\{ \tau^H_k \in \Gamma^H_k : P(\tau^H_k) = P_k \right\}
\]
and
\[
r_{k}^{\max} = \max_{\tau^H_k \in \Gamma^H_k} \{ \tau_b : P(\tau^H_k) \neq P_k \}.
\]

Proof: Any interval in which \( R_a \) is delayed can be considered as an alternating sequence of sub-intervals of two types:

(i) type X: if \( Q^{FRI} \) contains at least a request corresponding to a HW-task \( \tau^H_k \) with \( P(\tau^H_k) = P_k \) (i.e., same partition of \( \tau^H_k \)) waiting into \( Q^{FRI} \);

(ii) type Y: otherwise.

Note that these intervals have a different definition with respect to the ones used in the proof of Theorem 1, but the same properties apply (i.e., the classification is well defined). We proceed by considering each type separately.

Type X) Consider a single interval of type X. Because of the FIFO ordering of partition queues \( Q_k \), whenever \( R_a \) is delayed (during the considered interval), it must be waiting for the reconfiguration of HW-tasks with affinity \( P_k \) (present into \( Q^{FRI} \) by definition). According to Rule R-NP1 and Rule R-NP2, their corresponding request (or \( R_a \) itself) can be delayed by (i) other requests with lower (or equal) ticket time that are into \( Q^{FRI} \); and (ii) at most one request with higher ticket time which is (non-preemptively) served by the FRI. Because of the FIFO ordering of partition queue \( Q_k \), this latter request must be related to a HW-task with affinity \( \neq P_k \). In case (i), the same consideration argued in the proof of Theorem 1 holds (preemptive FRI). In case (ii), the delay suffered by \( R_a \) cannot be higher than \( r_{k}^{\max} = \max_{\tau^H_k \in \Gamma^H_k} \{ \tau_b : P(\tau^H_k) \neq P_k \} \) time units. By Rule R-NP2, such a delay can occur at most once for each interval of type X.

The total number of intervals of type X is maximized when, during each of such intervals, there is only one request into \( Q^{FRI} \) that corresponds to a HW-task with affinity \( P_k \). Hence, such a number is bounded by the total number of HW-tasks with affinity \( P_k \), given by \( N H_k^{\max} = \left\{ \tau^H_k \in \Gamma^H_k : P(\tau^H_k) = P_k \right\} \). Hence, the total delay in case (ii) across all intervals of type X is upper-bounded by \( N H_k^{\max} \times r_{k}^{\max} \).

Type Y) By definition, \( Q^{FRI} \) contains no requests corresponding to HW-tasks with the same affinity of \( \tau^H_k \). This clearly implies that \( R_a \) is either completed (and hence not yet delayed) or waiting inside \( Q_k \). This is the same situation discussed in the proof of Theorem 1 when considering the term \( \Delta^Y \).

In summary, the total delay suffered by \( R_a \) in intervals of type Y, plus the delay in case (i) during intervals of type X, is bounded by the upper-bound \( \Delta_a^P \) of the delay suffered under preemptive FRI management. Hence, the theorem follows.

V. PRACTICAL VALIDATION AND PROFILING

This section presents a preliminary case study implemented on the Zynq-7000 platform to evaluate the feasibility of the proposed approach, profile hardware acceleration speedup factors, and measure reconfiguration overheads. The considered platform includes a dual-core ARM Cortex-A9 processor and a 7-series FPGA integrated on the same chip. The internal structure of a Zynq SoC can be divided in two main functional blocks referred to as processing system (PS) and programmable logic (PL) [14]. The PS block comprises the ARM Cortex-A9 MPCore, the memory interfaces and the I/O peripherals, while the PL block includes the FPGA programmable fabric. The subsystems included in the PS are interconnected among themselves and to the PL through an ARM AMBA AXI (Advanced eXtensible Interface) interconnect.

The hardware modules configured on the PL can access the interconnect through a set of master and slave AXI interfaces exported by the PS side to the PL side. Slave interfaces allow modules to access the global memory space and share the DRAM memory with the processors. Dynamic partial reconfiguration is supported under the PS control. PL fabric can be fully or partially (re)configured by the PS through the device configuration interface (DevC) subsystem. The DevC includes a DMA engine that can be programmed to transfer bitstreams from the main memory to the PL configuration memory through the processor configuration access port (PCAP).

A. System architecture

In the prototype developed for the case study, the PL area is divided in two main regions: a static region and a reconfigurable region. The static region contains the communication infrastructure and other support modules, while the reconfigurable region is organized as a single partition divided into \( S \) slots, each hosting a HW-task.

In general, since bitstream relocation is not supported by the Xilinx standard tools [25] [26], each HW-task \( \tau^H \) is
implemented as a set of $n_j^S$ bitstreams, one for each slot $S_j$ of its associated partition $P(\tau^H_j)$. Each slot $S_j$ can accommodate all the specific implementations of each HW-task $\tau^H_i$ that belongs to partition $P(\tau^H_i)$.

Since the slot interface should match the one of the HW-tasks [26], we have defined a common interface that all HW-tasks are required to implement. Such a common interface is similar to the one adopted by Sadri et al. [29]. The interface includes an AXI master interface for accessing the system memory, an AXI slave interface through which the HW-task can be controlled by the PS, and an interrupt signal to notify the PS. The AXI master interface logic allows HW-tasks to retrieve data autonomously from the memory space, implementing the communication mechanism described in Section III-D.

In the current experimental setup, the AXI master interfaces exported by the HW-tasks are attached to high-performance slave ports exported by the PS, while the AXI slave control interfaces are attached to the general purpose master ports. The software part consists of a user-level library for the FreeRTOS operating system. The library abstracts the reconfiguration mechanism and provides a simple API that enables SW-tasks to request the execution of HW-tasks on the PL through the `EXECUTE_HW_TASK()` function, as described in Figure 2.

B. Experimental setup

The prototype has been deployed on a ZYBO board, featuring the Z-7010 Zynq SoC supported by 512 MB of DDR3 memory. The ARM cores included in the PS run at 650 MHz while the clock frequency for the PL is set to 100 MHz. In this experimental setup the single reconfigurable partition has been divided in two slots, each containing about 25% of the `slices` available in the programmable logic. The remaining 50% of the resources are allocated to the static part. Since both slots have the same dimensions, also the partial bitstreams resulting from the logic synthesis process have the same size of 338 KByte. Therefore, a large number of partial bitstreams can be stored in the 512 MB RAM memory.

The developed case study includes four standard functions implemented both as HW-tasks and software code: three simple image convolution filters (Sobel, Blur, and Sharp) and a matrix multiplier. The HW-tasks have been designed with the Xilinx Vivado® high-level synthesis tool, while the software versions have been implemented in C language. The image processing HW-tasks process images of size $800 \times 600$ pixels, with 24-bit color depth. The matrix multiplier HW-task has been synthesized to multiply 512 elements integer matrices.

C. Experimental results

1) Speedup evaluation experiment: A first experiment has been carried out to measure the speedup factors achievable from hardware acceleration on FPGA. The longest observed execution times (LOET) of the four HW-tasks have been measured and compared against the execution times of their software counterparts over 1000 runs. The results are reported in Table III. The minimum speedup has been computed as the ratio between the minimum software execution time and the maximum hardware execution time observed. Despite the clock frequency (100 MHz) of the FPGA was slower than the one of the processor (650 MHz), hardware accelerated implementations provided a relevant speedup between 5 and 15 over their software counterparts.

SPEEDUP EVALUATION.

2) Response time experiment: A second experiment was carried out to evaluate the longest observed response times in a scenario where the number of HW-tasks exceeds the number of slots. The task set used for this test includes four SW-tasks that use the four HW-tasks defined in Section V-B. SW-tasks are assigned priorities according to the rate-monotonic algorithm. Table IV summarizes the task parameters and the longest observed response times in a 8-hour run.

Considering the software execution times profiled in the previous experiment, it is worth noticing that the task set used for this experiment can only be scheduled through hardware acceleration. The equivalent task set, implemented as purely software tasks, with the same periods and priorities, it is clearly not schedulable on the processor.

Table IV

LONGEST OBSERVED RESPONSE TIMES.

Figure 6 shows the distribution of the reconfiguration times observed in the previous scheduling test for more than 500,000 reconfiguration events. The longest observed reconfiguration time is 2.845 ms. Therefore, given the size of the bitstreams, the minimum observed throughput of the PCAP configuration port resulted to be 116 MB/s, which is consistent with the maximum throughput of 145 MB/s stated by Xilinx [14].

It is worth mentioning that the set of four HW-tasks used for this experiment cannot be implemented statically using only 50% of the resources available on the the PL fabric. Partial reconfiguration allows to virtually extend the number of resources to accommodate all the HW-tasks in timesharing.

Overall, this case study has shown that, despite reconfiguration times are not negligible, the proposed approach can be implemented using current FPGA technology to improve the performance of real-time applications with respect to a pure software implementation.
VI. EXPERIMENTAL RESULTS

This section presents a set of experiments aimed at evaluating the performance of the FRED scheduling infrastructure in terms of schedulability analysis with synthetic workload. The experiments are performed to verify the schedulability under different architecture configurations and are obtained applying the sufficient response time analysis presented in Section IV.

A. Task set and architecture generation

The synthetic workload has been generated as follows.

1) Hardware architecture: The FRI throughput is defined as \( \rho = 100 \) and the total number of logic blocks is set as \( b = 1,000,000 \): the ratio between these two values yields an FRI throughput similar to the one observed in Section V. The logic blocks of the FPGA are equally distributed among the partitions. The same holds for the logic blocks of each partition, which are equally distributed among its slots.

2) SW and HW-tasks: For simplicity, we focus on the case where each SW-task accesses a single HW-task, i.e., \( m_i = 2, \forall \tau_i \in \Gamma^S \). Because of this restriction, we denote HW-tasks with the same index of the corresponding SW-task (i.e., \( \tau_i^H \) is the HW-task used by SW-task \( \tau_i \)). For each partition \( P_k \), a bucket of possible task periods is defined according to the following rules: (i) the interval of periods covered by any two buckets do not overlap; (ii) all the values in every bucket are in the range \([10^5, 10^6]\) \( \mu s \). For each SW-task \( \tau_i \), a random period \( T_i \) is chosen from the bucket corresponding to partition \( P(\tau_i^H) \) and then removed from the bucket. The UUniFast algorithm [30] is used to generate the utilization factor \( U_i \) of each SW-task \( \tau_i \), such that \( \sum_{\tau_i \in \Gamma^S} U_i = U \), where \( U \) is parameter defined in the experiments. The minimum task utilization is set to \( U_{\text{min}} = 0.005 \). The WCET of each SW-task \( \tau_i \) is then computed as \( C_i = U_i \cdot T_i \). Such a value has been then randomly split to obtain the WCETs \( C_{i,1} \) and \( C_{i,2} \) of each sub-task. Finally, a parameter \( U^H \) has been defined to “mimic” a notion of utilization of the FPGA (also referred to as hardware utilization). Note that, due to the intrinsic interaction between SW- and HW-tasks, this parameter cannot be related to a pure concept of utilization like the parameter \( U \). Again, the UUniFast algorithm [30] algorithm was used to generate the hardware utilization for each hardware task as follows: \( \forall \tau_i^H \in \Gamma^H, C_i^H = U_i^H \cdot T_i \). Like \( U \), \( U^H \) is another parameter varied in the experiments. Task priorities \( \pi_i \) are assigned according to the rate-monotonic policy.

B. Experiments on schedulability analysis

This set of experiments has been carried out to measure the schedulability ratio of the tested task sets under four different configurations:

(i) Static: the FPGA is supposed to have an infinite area, so that all the HW-tasks are statically assigned to a fixed slot, thus reconfiguration is not needed.

(ii) FRED-P: the proposed approach is used with preemptive FRI management and scheduling delays are computed according to Theorem 1;

(iii) FRED-NP: same as FRED-P but with non-preemptive FRI management and delays computed by Theorem 2;

(iv) Software: all task sets are implemented in software. Worst-case execution times of the resulting software implementation of HW-tasks are computed considering a speed-up factor \( \Phi \), assumed to be the same for all the HW-tasks.

A first experiment varied the utilization \( U \) of a fixed number of tasks (both HW and SW), using \( n_P = 3 \) partitions, each with \( n_k^S = 2 \) slots, and 3 HW-tasks with affinity to each partition. The total number of tasks \( n_S \) has been chosen to overload the system: each partition \( P_k \) has \( n_k^S + 1 \) tasks, hence all the tested task sets are not feasible without enabling DPR. Figure 7 reports the results of an experiment where \( U \) was varied from 0.05 to 0.95 with a step of 0.05, with \( \Phi = 1 \) and \( U^H = 0.1 \). Please keep in mind that the small value of \( U^H \) cannot be interpreted as in the classical software semantics.

---

As evident from the plots, the Software approach quickly degrades at utilization values that are much lower than the ones at which FRED-P and FRED-NP starts being no more able to schedule the task sets. Even with an unrealistic and limist-case value for the speed-up (\( \Phi = 1 \)), this happens because the FPGA allows for intrinsic parallelism with respect to a single processor. The small difference between FRED-P and FRED-NP is due to the fact that the reconfiguration time (chosen according the profiling of Section V) results almost negligible with respect to the generated execution times of HW-tasks. The Static approach represents a theoretical upper-bound (i.e., not practically achievable because assumes FPGAs with infinite area), whose performance depends on the absence of reconfiguration times and contention for slots and the FRI. In this experiment FRED obtains a schedulability ratio higher than 50% up to \( U = 0.6 \), outperforming the pure Software approach. Moreover, the results are quite close to the ideal scenario provided by a fully Static approach.

Figure 8 reports the result of another experiment where the software utilization has been fixed to \( U = 0.1 \) and \( U^H \) has been varied from 0.05 to 0.95 with a step of 0.05. Also in this case, FRED outperforms pure Software approach, guaranteeing more than 50% of the tested task sets up to \( U^H = 0.4 \).
A third experiment has been carried out to investigate the benefits of FRED for applications that fully saturate the FPGA area and hence cannot be extended to include additional tasks without exploiting DPR. We considered systems with 2 partitions, 2 slots per partition and $\Phi = 3$. Starting from a fixed scenario ($U^H = 0.1, U = 0.1$) where all the slots are occupied by HW-tasks, Figure 9 reports the schedulability ratio obtained by adding $n_A$ new tasks (each consisting of a SW-task and the corresponding HW-task), where $n_A$ was varied from 0 to 12. Each added task $\tau_i$ has $U^H = 0.05$ and $U_i = 0.05$, while the other parameters were generated as in the previous experiments. The affinity of each new task was chosen as specified in Section VI-A2. This experiment clearly shows that FRED allows guaranteeing real-time applications extended with more than 5 tasks, which otherwise could not be executed.

VII. CONCLUSIONS

This paper presented a framework for supporting the development of safety-critical real-time applications on computing platforms that include a processor and an FPGA module with dynamic partial reconfiguration capabilities.

After providing a model of the platform and the computational activities, a scheduling infrastructure was proposed to bound the delays experienced by the tasks, and a response-time analysis was derived to verify the schedulability of safety-critical applications with real-time constraints. The approach has also been implemented and validated on the Zynq platform to demonstrate its practical applicability. The experimental results performed on synthetic workloads showed the performance of the analysis in different scenarios.

As a future work, we plan to incorporate the proposed framework inside the Erika Enterprise operating system, providing specific system call that simplify the development of safety-critical real-time applications on heterogeneous computing platforms using FPGA accelerated components.

ACKNOWLEDGEMENTS

The authors like to thank Geoffrey Nelissen for his valuable support in setting up the analysis for self-suspending tasks.
