I. INTRODUCTION

Linux is a general purpose operating system (GPOS) that has gained many real-time (RT) features over the last decade. For instance, nowadays Linux has a \textit{fully preemptive} mode and a deadline-oriented scheduler \cite{1}. Although some of these features are part of the official Linux kernel, many of them are still part of an external patch set, the PREEMPT-RT \cite{2}. The PREEMPT-RT changes the locking methods of Linux to prevent unbounded priority inversion. This is achieved by using the Priority Inheritance Protocol \cite{3} on in-kernel mutexes, which bounds the activation delay in high priority tasks. Indeed, the \textit{latency} is the main evaluation metric for the PREEMPT-RT Linux: for example, the Red Hat Enterprise Linux for Real-time \cite{4} (based on PREEMPT-RT) shows a maximum latency of 150 \mu s on certified hardware. However, due to Linux’s GPOS nature, RT Linux developers are challenged to provide the predictability required for an RTOS, while not causing regressions on the general purpose benchmarks. As a consequence, the implementation of some well known algorithms, like read/write semaphores, has been done using approaches that were not well explored in academic papers.

II. READ-WRITE SEMAPHORES ON LINUX

On Linux, the read-write semaphores provide concurrent readers and exclusive writers for a given critical section. For example, since the memory mapping information of a process is read very often but rarely changes during its execution, it is protected by a read-write semaphore.

The API of the read-write semaphores is composed by four main functions. Readers call \texttt{DOWN_READ()} before entering in the read-side, calling \texttt{UP_READ()} when leaving the read-side of the critical section. Writers should call \texttt{DOWN_WRITE()} before entering in the write-side of the critical section, calling \texttt{UP_WRITE()} when leaving. These functions take only one argument, which is a pointer to a structure \texttt{rw_semaphore}. The \texttt{rw_semaphore} structure is presented in Figure 1\textsuperscript{1}.

The \texttt{readers} variable is an atomic type that counts how many concurrent readers are inside the critical section. This variable is also used to store \texttt{READER BIAS} and \texttt{WRITER BIAS} flags, which are used to define if there are either readers or a writer in the critical section. Whenever a task should block in the semaphore, it will do by blocking in the real-time mutex \texttt{rt_mutex} of the semaphore. The \texttt{rt_mutex} is defined as shown in Figure 2\textsuperscript{1}.

![Fig. 1: Read-write Semaphore structure](image1)

![Fig. 2: Real-time Mutex structure](image2)

In order to protect the fields of the \texttt{rt_mutex} struct from concurrent accesses, the spin lock \texttt{wait_lock} is used whenever the internal fields of the mutex are modified. The \texttt{wait_lock} of the real-time mutex is also used to avoid two writers setting the \texttt{WRITE/READ BIAS} concurrently in the \texttt{rw_semaphore} structure.

The pseudo-code of each operation is presented in Figure 3 and 4, respectively.

III. OPEN PROBLEMS

Considering our example, when \texttt{DOWN_WRITE()} is called, the task that is trying to acquire the read/write semaphore for writing has to lock two nested resources, a regular \texttt{mutex} (acquired at line 8, Figure 4) and a \texttt{spin lock} (acquired at line 14, Figure 4), thus creating a \textit{heterogeneous nested lock} (e.g., a suspension-based lock with a nested spin-based lock or vice-versa). This case study, taken from the Linux kernel, highlights two open issues. The first one concerns the need for implementing

\textsuperscript{1}Debug fields removed from structure’s definition.
in Linux state-of-the-art protocols for (possibly heterogeneous) nested locks and developing novel analysis techniques. To the best of our knowledge, only few works on shared-memory multiprocessor synchronization targeted nested critical sections. Two notable examples are the work by Biondi et al. [5], in which a graph abstraction is introduced to derive a fine-grained analysis (i.e., not based on asymptotic bounds) for FIFO non-preemptive spin locks, and the one by Ward and Anderson [6], in which the real-time nested locking protocol (RNLP) is proposed, with the related asymptotic analysis. Later, Nemitz et al. [7] proposed an optimization for the average-case of RNLP. However, to the best of our knowledge, only the extension of RNLP proposed in [8] is explicitly conceived to deal with heterogeneous nested critical sections. The protocol is presented with the related asymptotic analysis, and an experimental study aimed at assessing schedulability. Future research work could target the issues in implementing the extended RNLP [8] in Linux. Also, it is worth considering the possibility of extending the graph abstraction proposed by Biondi et al. [5] to allow fine-grained analysis for nested heterogeneous locks.

The second open problem concerns the design of specialized analysis techniques accounting for specific implementations of complex types of locks (e.g., the aforementioned read/write lock in Linux). Considering the problem previously presented for the DOWN_WRITE function, an implementation-aware analysis would account for the contention on the heterogeneous nested critical section, considering it when a blocking-bound for the reader/writer semaphore is derived. The analyses for reader/writer semaphores that have already been proposed (e.g., the protocol proposed by Brandenburg and Anderson [9], or R/W RNLP [10], a variant of RNLP conceived to deal with nested, spin-based, read/write locks) could be integrated with implementation-specific aspects. The availability of blocking-bounds conceived considering the specific implementation adopted in the Linux kernel may help it to be more suitable for real-time contexts. Finally, a third open research area consists in finding more efficient locking protocols (with the related implementation), accounting for both general purpose benchmark performance (i.e., average-case behavior, needed by the GPOS nature of Linux) and predictability.
